Un cas réel d’aide à la décision :
comparer des scenarios de transport.

Résumé

Ce document présente une étude sur un problème réel de comparaison de scénarios de transport pour l’établissement de la politique concernant le trafic maritime en Grèce. Le document présente la situation problématique et la formulation relative du problème. Ensuite, le modèle d’évaluation est présenté en détail. Il s’agit d’un modèle hiérarchique qui permet de prendre en compte les multiples dimensions et points de vue des parties prenants concernées.

A real case study on
Transportation Scenario Comparison.

Abstract

This paper presents a real case study dealing with the comparison of transport scenarios. The study is conducted within a larger project concerning the establishment of the maritime traffic policy in Greece. The paper presents the problem situation and an appropriate problem formulation. Moreover a detailed version of the evaluation model is presented in the paper. The model consists of a complex hierarchy of evaluation models enabling us to take into account the multiple dimensions and points of view of the actors involved in the evaluation.
1 Introduction

Strategic planning of transportation facilities is an increasingly important issue in market oriented economies. The paper describes a real case study dealing with the evaluation of transportation scenario in the context of the deregulation of the maritime traffic in Greece (after the European Union guidelines).

Comparing and evaluating policies is not simple. The interested reader might see Stathopoulos, 1997 and Faivre d’Arcier, 1998. Besides the usual uncertainty issues it should be noted that a scenario results from the composition of a large number of actions (see Pomerol, 2000). Even if each such action can be evaluated alone there might be a combinatorial explosion in trying to evaluate the different scenarios. On the other hand, a comparison should be able to highlight the key differences among the different scenarios. Further on it should be able to take into account the different points of view and the different dimensions under which the policy makers consider such scenarios. In the precise case of transportation scenarios, on the one hand there exist large groups of actors concerned by transportation policies which cannot be neglected and on the other hand each point of view is usually by itself a complex evaluation model. Actually the case studied in this paper results in an hierarchy of evaluation models that compose the comprehensive evaluation model.

The research has been conducted within a large project aiming at building a decision support system for the analysis and evaluation of the maritime transportation policy in Greece. In this paper we do not discuss how the scenarios are composed (considering that they are defined by the policy maker or the user of the decision support system). We also consider that the evaluation dimensions suggested are “effective” in the sense that there exists the necessary information for all of them.

The paper is organised as follows. In section 2 we describe the problem situation and the potential users of the model. In section 3 we introduce the problem formulation as it has been conceived after a number of discussions with the potential users. Section 4 contains an extensive description of the evaluation model. Such a model is structured in an hierarchy, each node of which is analysed in section 4. The conclusive section discusses the model and indicates the next steps of the research.

2 Problem Situation

The maritime transportation network in the Aegean sea represents a big challenge for the policy makers of the Greek government and the administration. The “deregulation” foreseen for the year 2002 will introduce a further turbulence in an already critical situation. The model introduced is part of a larger project aiming at aiding the Greek policy makers of the sector and the relevant actors to better understand
the consequences of their actions on such a network. More specifically it should
help in evaluating specific actions altering the configuration of the network. Who
is the potential user of the comparison module? A highly ranked administrative
and/or political officer. The model (as well as the whole project) should be ex-
pected to be used both in “everyday” policy establishment and in strategic plan-
ing. We consider that such a potential user will use the comparison module for
three main purposes:
- to justify (whenever possible) a number of administrative actions and political
statements;
- to explain (at least partially) the behaviour of the relevant actors operating on the
network;
- to argue (for or against) a number of actions of other relevant actors operating on
the network.

Methodological Considerations

A scenario comparison module in a Decision Support System should represent
the preferences of an end-user (normally the client; see Landry et al., 1985, Vincke,
1992). The specific setting of this system did not define such an end-user, reason
for which a number of hypothesis substitute the client’s preferences in the problem
formulation and the evaluation model.

In other terms we assumed a prescriptive point of view considering a generic
end-user with a rational model on the management of the maritime network (see
Bell et al., 1988). Such a prescriptive approach is materialised through a number
of “arbitrary” hypothesis, namely:
- in the definition of the reasons under which a given network configuration \( X \) can
be considered better, or at least as good as, a network configuration \( Y \) for each
leave of the hierarchy of criteria (hereafter \( X \) and \( Y \) will always represent network
configurations; we will always omit to specify that, unless necessary);  
- in the definition of the coalitions of criteria enabling to establish whether \( X \) is
at least as good as \( Y \) in the parent nodes of the hierarchy (hereafter denoted as
“winning coalitions”).

Nevertheless the end-user should be allowed to modify the parameters adopted
in such a prescriptive approach in order to implement his(her) own policy. Under
such a perspective we consider that in the implementation of the final version of
the system it should be possible to:
- allow a technical end-user to modify the technical evaluations and comparison
procedures at the leaves of the hierarchy;
- allow a political end-user to modify the definition of winning coalitions in any
parent node of the hierarchy.
3 Problem Formulation

Consider the maritime transportation network of the Aegean sea (hereafter called the network) as configured in a given moment. Consider a set of actions that could be undertaken on such a network modifying either the supply conditions, or the demand or both. For each such modification a new configuration of the network can be considered as a result of the “simulation module” of the project.

1. The set of alternatives to be considered in the evaluation module is represented by such different configurations of the network.

2. The set of points of view to consider represents the points of view of the relevant actors operating on the network as strategically conceived by the potential user of the module. Such points of view are expected to be structured in an hierarchy of criteria.

3. The problem statement is a relative comparison of such configurations under a ranking purpose. However, it should be noticed that due to the low number of alternatives that effectively are considered altogether at the same time it could be expected that the main purpose of the comparison module will be the comparison itself than the ranking.

4 Evaluation Model

In the following we will concentrate our attention to the construction of the set of criteria. The set of alternatives corresponds to a number of potential configurations of the network following specific scenarios of actions.

4.1 Top-down analysis of the criteria set

At the first general level we consider three criteria corresponding to three types or groups of actors, the opinion of which is a concern of the user.

1. Quality of the supply. The criterion should represent the preference of a generic individual (un-distinguishable) user of the network. The idea is that such a user will prefer any network configuration providing faster, safer and reliable connections.

2. Network Efficiency. Under such a criterion we evaluate whether network A is at least as good as network B as far as two main actors of the network are concerned: the ship owners and the government, under an “economic” point of view.
3. Demand Satisfaction. Such a criterion should consider the satisfaction of three groups of users of the network: the tourists, the residents and the carriers. We consider here the satisfaction of social groups and not of single users.

Criterion 1 is further decomposed in five criteria evaluating the quality of the supply:
1.1: frequency;
1.2: availability of direct connections;
1.3: perceived cost;
1.4: ship quality;
1.5: port quality.
In order to evaluate Frequency, three criteria will be considered:
1.1.1: week availability;
1.1.2: week distribution;
1.1.3: daily distribution.

Criterion 2 is further decomposed in two criteria:
2.1: efficiency of the private sector;
2.2: efficiency of the public sector.
For both cases we analyse lines exploitation and port exploitation:
2.1.1: efficiency of private lines;
2.1.2: efficiency of private ports (if any);
2.2.1: efficiency of public subsidised lines (if any);
2.2.2: efficiency of port administration.
Three types of ports are considered: national, regional and local ones. We therefore have:
2.1.2.1: efficiency of national private ports (if any);
2.1.2.2: efficiency of regional private ports (if any);
2.1.2.3: efficiency of local private ports (if any);
2.2.2.1: efficiency of national ports administration;
2.2.2.2: efficiency of regional ports administration;
2.2.2.3: efficiency of local ports administration;

Criterion 3 is further decomposed into three criteria representative of the three groups the satisfaction of which has to be considered:
3.1: residents (R)-demand;
3.2: tourists (T)-demand;
3.3: carriers (C)-demand.
For each of such groups we consider two criteria: one concerning the quantitative satisfaction of the demand, the second concerning a qualitative level of satisfaction (how many “important” connections are satisfied), obtaining:
3.1.1: Quantitative (R)-demand;
3.1.2: Qualitative (R)-demand;
3.2.1: Quantitative (T)-demand;
3.2.2: Qualitative (T)-demand;
3.3.1: Quantitative (C)-demand;
3.3.2: Qualitative (C)-demand.

The final hierarchy is shown in figure 1.

4.2 Bottom-up analysis of the evaluation model

1.1.1 Consider the network as an \( n \times n \) matrix (\( n \) being the ports considered in the network). We consider matrix \( N_0 \) where element \( x^0_{ij} \) denotes the number of direct connections weekly available between nodes \( i \) and \( j \) of the network. In the same way we consider matrix \( N_1 \) (\( x^1_{ij} \) being the number of connections weekly available between nodes \( i \) and \( j \) of the network using one intermediate connecting port) and matrix \( N_2 \) (\( x^2_{ij} \) being the number of connections weekly available between nodes \( i \) and \( j \) of the network using two intermediate connecting ports). We denote by \( N_t = N_0 + N_1 + N_2 \) the matrix whose generic element \( x^t_{ij} \) denotes the number of connections weekly available between nodes \( i \) and \( j \) of the network using at most two intermediate connecting ports.

We consider only the upper (or lower) triangular part of \( N_t \) under the hypothesis that usually the number of connections between \( i \) and \( j \) is symmetric. If it is not the case we take the minimum between the two numbers. We denote the cardinal of the upper triangular part of matrix \( N_t \) as \( |N_t| \). From matrix \( N_t \) we are able to compute a diagram of frequencies as follows:
- \( n^1_t \): number of couples in \( N_t \) having less than 5 connections weekly;
- \( n^2_t \): number of couples in \( N_t \) having less than 10 and more than 5 connections weekly;
- \( n^3_t \): number of couples in \( N_t \) having less than 30 and more than 10 connections weekly;
- \( n^4_t \): number of couples in \( N_t \) having less than 50 and more than 30 connections weekly;
- \( n^5_t \): number of couples in \( N_t \) having less than 100 and more than 50 connections weekly;
- \( n^6_t \): number of couples in \( N_t \) having more than 100 connections weekly.

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) (\( X \succ Y \)) iff:

\[
\frac{n^1_t(X)}{|N_t|} < \frac{n^1_t(Y)}{|N_t|} \quad \text{OR} \quad \frac{n^1_t(X)}{|N_t|} < \frac{n^1_t(Y)}{|N_t|}
\]
Figure 1: The hierarchy of criteria
Consider again matrix \( M \) most two intermediate connecting ports. We are now able to compute a new denoting matrix \( m \).

Consider two alternatives \( X \) and \( Y \) (to be compared with Dubois and Prade, 1983). The reader should note that, due to the fact that \( \sum_{i=1}^{n} \frac{n_i(X)}{|N_i|} \leq 1 \), if \( \frac{n_i(X)}{|N_i|} < \frac{n_i(Y)}{|N_i|} \), then there exists a \( j > i \) for which \( \frac{n_j(X)}{|N_j|} > \frac{n_j(Y)}{|N_j|} \). Further on, if \( \forall i < 6 \frac{n_i(X)}{|N_i|} = \frac{n_i(Y)}{|N_i|} \), then also \( \frac{n_6(X)}{|N_6|} = \frac{n_6(Y)}{|N_6|} \). Therefore the comparison procedure guarantees that \( X \) will be considered better than \( Y \) iff effectively the supply of \( X \) is better than the one in \( Y \).

1.1.2 Consider again matrix \( N_l \). Such a matrix can be viewed as the sum of \( N_{1l} + N_{2l} + \ldots + N_{7l} \) where \( N_{1l} \) denotes matrix \( N_l \) for day 1 (Monday), \( \ldots N_{7l} \) denoting matrix \( N_l \) for day 7 (Sunday). \( N_{lt} \) will denote matrix \( N_l \) for the generic day \( l \) of the week. Therefore, element \( x_{ij}^{lt} \) will denote the number of connections available in day \( l \) between nodes \( i \) and \( j \) of the network using at most two intermediate connecting ports. We are now able to compute a new matrix \( M_l \) where the generic element

\[
y_{ij}^l = \frac{\max(x_{ij}^{lt}) - \min(x_{ij}^{lt})}{\max(x_{ij}^{lt})}
\]

\( y_{ij}^l = 1 \) is the worst case since it denotes the existence of a situation where there are days with a maximum of supply and days with no supply at all.

\( y_{ij}^l = 0 \) is the best case since it denotes the existence of a situation where the supply is the same all days.

From matrix \( M_l \) we are able to compute a diagram of frequencies as follows:
- \( m_1^l \): number of couples in \( M_l \) such that \( y_{ij}^l \leq 0.2 \);
- \( m_2^l \): number of couples in \( M_l \) such that \( 0.2 < y_{ij}^l \leq 0.4 \);
- \( m_3^l \): number of couples in \( M_l \) such that \( 0.4 < y_{ij}^l \leq 0.6 \);
- \( m_4^l \): number of couples in \( M_l \) such that \( 0.6 < y_{ij}^l \leq 0.8 \);
- \( m_5^l \): number of couples in \( M_l \) such that \( 0.8 < y_{ij}^l \leq 1 \).

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) (\( X \succ Y \)) iff:

\[
\frac{n_1^l(X)}{|N_l|} > \frac{n_1^l(Y)}{|N_l|} \quad \text{OR}
\]
Consider matrix 

\[ \frac{m_1^k(X)}{|M_t|} = \frac{m_1^k(Y)}{|M_t|} \text{ and } \frac{m_2^k(X)}{|M_t|} > \frac{m_2^k(Y)}{|M_t|} \text{ OR } \frac{m_1^k(X)}{|M_t|} = \frac{m_1^k(Y)}{|M_t|} \text{ and } \frac{m_2^k(X)}{|M_t|} = \frac{m_2^k(Y)}{|M_t|} \text{ and } \frac{m_3^k(X)}{|M_t|} > \frac{m_3^k(Y)}{|M_t|} \text{ OR } \ldots \]

\[ z_{ij}^k = \frac{\max_i(x^h_{ij}) - \min_i(x^h_{ij})}{\max_i(x^h_{ij})} \]

\[ z_{ij}^k = 1 \text{ is the worst case since it denotes the existence of a situation where there are slots with a maximum of supply and slots with no supply at all.} \]

\[ z_{ij}^k = 0 \text{ is the best case since it denotes the existence of a situation where the supply is the same in all slots.} \]

From matrix \( K_t \) we are able to compute a diagram of frequencies as follows:

- \( k_1^1 \): number of couples in \( K_t \) such that \( z_{ij}^1 \leq 0.2 \);
- \( k_2^1 \): number of couples in \( K_t \) such that \( 0.2 < z_{ij}^1 \leq 0.4 \);
- \( k_3^1 \): number of couples in \( K_t \) such that \( 0.4 < z_{ij}^1 \leq 0.6 \);
- \( k_4^1 \): number of couples in \( K_t \) such that \( 0.6 < z_{ij}^1 \leq 0.8 \);
- \( k_5^1 \): number of couples in \( K_t \) such that \( 0.8 < z_{ij}^1 \leq 1 \).

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) \((X \succ Y)\) iff:

\[ \frac{k_1^1(X)}{|K_t|} > \frac{k_1^1(Y)}{|K_t|} \text{ OR } \frac{k_1^1(X)}{|K_t|} = \frac{k_1^1(Y)}{|K_t|} \text{ and } \frac{k_2^1(X)}{|K_t|} > \frac{k_2^1(Y)}{|K_t|} \text{ OR } \frac{k_1^1(X)}{|K_t|} = \frac{k_1^1(Y)}{|K_t|} \text{ and } \frac{k_2^1(X)}{|K_t|} = \frac{k_2^1(Y)}{|K_t|} \text{ and } \frac{k_3^1(X)}{|K_t|} > \frac{k_3^1(Y)}{|K_t|} \text{ OR } \ldots \]

\[ \text{NB. The same reasoning concerning the properties of the lexicographic comparison applies here also.} \]
1.1 Consider two network configurations $X$ and $Y$. Then $X$ is at least as good as $Y$ under criterion 1.1 ($X \succeq_{1,1} Y$) iff:
- $\forall j, X \succeq_{1,1,j} Y$ OR
- $X \succeq_{1,1} Y$ and $X \succeq_{1,1,2} Y$.

In other words in order to be $X$ at least as good as $Y$ as far as the frequency criterion is concerned, it has to be the case for both criteria 1.1.1 (week availability) and 1.1.2 (week distribution).

1.2 Consider again matrix $N_0$. In such a matrix we consider only direct connections. From such a matrix we are able to compute a diagram of frequencies as follows:
- $d_1^t$: number of couples in $N_0$ having less than 5 connections weekly;
- $d_2^t$: number of couples in $N_0$ having less than 10 and more than 5 connections weekly;
- $d_3^t$: number of couples in $N_0$ having less than 30 and more than 10 connections weekly;
- $d_4^t$: number of couples in $N_0$ having less than 50 and more than 30 connections weekly;
- $d_5^t$: number of couples in $N_0$ having less than 100 and more than 50 connections weekly;
- $d_6^t$: number of couples in $N_0$ having more than 100 connections weekly.

Consider two alternatives $X$ and $Y$. Then $X$ is better than $Y$ ($X \succ Y$) iff:

$$\frac{d_1^t(X)}{|N_0|} < \frac{d_1^t(Y)}{|N_0|} \quad {\text{OR}} \quad \frac{d_2^t(X)}{|N_0|} < \frac{d_2^t(Y)}{|N_0|} \quad {\text{OR}} \quad \frac{d_3^t(X)}{|N_0|} < \frac{d_3^t(Y)}{|N_0|}$$

...etc...

**NB.** The same reasoning concerning the properties of the lexicographic comparison applies here also.

1.3 Consider matrix $N_t$. For each couple of nodes $i, j$ with a non zero entry in the matrix we compute a generalised cost as follows:

$$c_{ij} = v_t \left( \sum_{x \in iP_j} t_x + \sum_{y \in iN_j} t_y + \sum t_P \right) + \sum x \in iP_j p_x$$

where:
- $t_x$: is the travelling time for arc $x$;
- $t_y$: is the connecting time for node $y$;
- $t_P$: is a penalty time for each connection;
- $p_x$: is the price (economy fair) for travelling through arc $x$;
- $iPj$: is the path (set of arcs) connecting node $i$ to node $j$;
- $iNj$: is the path (set of nodes) connecting node $i$ to node $j$;
- $v_t$ is the value of time.

We are now able to define a matrix $P_t$ containing the generalised costs for all couples of nodes. From matrix $P_t$ we are able to compute a diagram of frequencies as follows:

- $p_1^t$: number of couples in $P_t$ such that $c_{ij} \leq 1000$;
- $p_2^t$: number of couples in $P_t$ such that $1000 < c_{ij} \leq 5000$;
- $p_3^t$: number of couples in $P_t$ such that $5000 < c_{ij} \leq 10000$;
- $p_4^t$: number of couples in $P_t$ such that $10000 < c_{ij} \leq 20000$;
- $p_5^t$: number of couples in $P_t$ such that $20000 < c_{ij}$.

Consider two alternatives $X$ and $Y$. Then $X$ is better than $Y$ ($X \succ Y$) iff:

\[
\frac{p_5^t(X)}{|P_t|} < \frac{p_5^t(Y)}{|P_t|} \quad \text{OR} \quad \frac{p_4^t(X)}{|P_t|} < \frac{p_4^t(Y)}{|P_t|} \quad \text{OR} \quad \frac{p_3^t(X)}{|P_t|} < \frac{p_3^t(Y)}{|P_t|} \quad \text{OR} \quad \text{etc...}
\]

**NB.** The same reasoning concerning the properties of the lexicographic comparison applies here also.

1.4 For this criterion the basic information concerns the knowledge on the operating fleet. Set $V$ the set of all vessels operating on the network. We consider a frequency diagram as follows:

- $v^1$: number of vessels aged less than 5 years;
- $v^2$: number of vessels aged less than 10 years and more than 5;
- $v^3$: number of vessels aged less than 15 years and more than 10;
- $v^4$: number of vessels aged less than 20 years and more than 15;
- $v^5$: number of vessels aged less than 25 years and more than 20;
- $v^6$: number of vessels aged more than 25 years.

Consider two alternatives $X$ and $Y$. Then $X$ is better than $Y$ ($X \succ Y$) iff:

\[
\frac{v^6(X)}{|V|} < \frac{v^6(Y)}{|V|} \quad \text{OR}
\]
\[ \frac{v^6(X)}{|V|} = \frac{v^6(Y)}{|V|} \text{ and } \frac{v^5(X)}{|V|} < \frac{v^5(Y)}{|V|} \text{ OR } \]
\[ \frac{v^6(X)}{|V|} = \frac{v^6(Y)}{|V|} \text{ and } \frac{v^5(X)}{|V|} = \frac{v^5(Y)}{|V|} \text{ and } \frac{v^4(X)}{|V|} < \frac{v^4(Y)}{|V|} \text{ OR } \]

...etc...

**NB.** The same reasoning concerning the properties of the lexicographic comparison applies here also. The reader should also notice that we avoid to compute an average age of the fleet. The reason for such a choice is that the image of the fleet and the safety of travelling are always perceived by the users on the basis of the worst possible case. In order to be coherent with the sense of this criterion (how a generic user perceives the supply), we decided to adopt the above approach.

- In order to consider the port quality we take into account three dimensions:
  - capacity of the port;
  - existence of facilities for the passengers;
  - accessibility of the port (parking lots, roads, etc.).

The necessary information results from a survey conducted within the larger project part of which is this research report. From the available information we are able to give the following values for the capacity dimension:
- large (L: more than 3 vessels contemporaneously);
- average (A: 2 vessels contemporaneously);
- small (S: only one vessel possible).

The facilities are evaluated on a binary basis: they exist (Y) or not (N). Accessibility is evaluated on three values: good (G), average (A), bad (B).

The four classes of port quality are defined as follows:
- Good: \( G = \{(L,Y,G),(A,Y,G)\} \);
- Fair: \( F = \{(A,Y,A),(L,Y,A),(S,Y,A),(S,Y,G)\} \);
\( (L,N,A),(A,N,A),(S,Y,B),(S,N,G)\} \);
- Bad: \( B = \{(S,N,B),(L,N,B),(A,N,B),(S,N,A)\} \).

Then considering the set (complete or sample) of ports \( P \) we can again define a diagram of frequency:
- \( p_G \): number of ports of good quality;
- \( p_F \): number of ports of fair quality;
- \( p_A \): number of ports of acceptable quality;
- \( p_B \): number of ports of bad quality.

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) \( (X \succ Y) \) iff:

\[ \frac{p_G(X)}{|P|} > \frac{p_G(Y)}{|P|} \text{ OR } \]
Given two network configurations $X$ and $Y$ we have to establish whether $X$ is at least as good as $Y$ when all the five criteria defining the supply quality are considered. Our suggestion is that the “winning coalitions” enabling to establish the above statement are:

- the unanimity set (all the five criteria agree that $X$ is at least as good as $Y$);
- any coalition of four criteria (all criteria, but one, agree that $X$ is at least as good as $Y$);
- any coalition including criteria 1.3, 1.4 and one among the other ones.

Further on, no veto should be expressed against $X$. Such a veto may occur in the following situations (considering a set of alternative network configurations $\mathcal{F} = \{X, Y, Z, \ldots\}$):

- $X$ cannot be at least as good as $Y$ if $X$ is the worst on criterion 1.1 and $Y$ is the best;
- $X$ cannot be at least as good as $Y$ if $X$ is the worst on criterion 1.4 and $Y$ is the best.

In order to compute a ranking of set $\mathcal{F}$ associated with criterion 1, denote $S_1(X, Y)$ the binary relation “$X$ is at least as good as $Y$” on criterion 1 on set $\mathcal{F}$ and then compute a score:

$$\sigma(X) = |\{Y \in \mathcal{F} : S_1(X, Y)\}| - |\{Y \in \mathcal{F} : S_1(Y, X)\}|$$

and rank the alternatives by decreasing values of such score.

2.1.1 For this criterion we consider a set of (15) “lines” established by maritime administration authority. By “line” is intended a subset of connections on part of the network (usually corresponding to a precise geographical area). For each of such lines we know which company (vessel owner) and with which vessels operates. From the economic analysis of the existing network we are able to compute:

- $c_{ijl}$: cost of vessel $l$, of company $j$, on line $i$;
- $r_{ijl}$: income of vessel $l$, of company $j$, on line $i$.

We are therefore able to compute a cost $c_{ij}$ and income $r_{ij}$ for each line $i$ and company $j$ through the formula:

$$c_{ij} = \sum_l c_{ijl}, \quad r_{ij} = \sum_l r_{ijl}$$
We define as efficiency of company \( j \) on line \( i \) the index

\[
k_{ij} = \max(0, 1 - \frac{c_{ij}}{r_{ij}})
\]

In presence of a profitable exploitation of line \( i \) by company \( j \) the ration \( \frac{c_{ij}}{r_{ij}} \) tends to become the lowest possible. In order to invert the index we consider the complement of the ratio. In case of a loss the index could become negative, reason for which it is bounded to 0.

We are now able to compute an efficiency index for line \( i \) as \( e_i = \max_j(k_{ij}) \). In other words the efficiency of line \( i \) is the best possible among the competing companies on the same line.

For a given network configuration \( X \) we are able to compute an efficiency index \( E(X) \) as follows:

\[
E(X) = \text{median}(e_i(X))
\]

The use of the median is justified by its underlying concept of majority. If a network \( X \) has a better median than network \( Y \) then a “majority” of lines within \( X \) have a better efficiency index with respect to network \( Y \).

2.1.2.1 For each national level port privately administrated we can compute an efficiency index:

\[
\forall i \in N^P, \quad p_i = \max(0, 1 - \frac{c_i}{r_i})
\]

where:
- \( N^P \): is the set of national level ports privately administrated;
- \( c_i \): is the administration cost of port \( i \);
- \( r_i \): is the income of port \( i \).

We can therefore compute the index \( p_{NP} = \text{median}(p_i) \). If there are no national level ports privately administrated, we consider \( p_{NP} = 0 \).

2.1.2.2 For each regional level port privately administrated we can compute an efficiency index:

\[
\forall i \in R^P, \quad p_i = \max(0, 1 - \frac{c_i}{r_i})
\]

where:
- \( R^P \): is the set of regional level ports privately administrated;
- $c_i$: is the administration cost of port $i$;
- $r_i$: is the income of port $i$.

We can therefore compute the index $p_{RP} = \text{median}(p_i)$. If there are no national level ports privately administrated, we consider $p_{RP} = 0$.

2.1.2.3 For each local level port privately administrated we can compute an efficiency index:

$$\forall i \in L^P, \ p_i = \max_i (0, 1 - \frac{c_i}{r_i})$$

where:
- $L^P$: is the set of local level ports privately administrated;
- $c_i$: is the administration cost of port $i$;
- $r_i$: is the income of port $i$.

We can therefore compute the index $p_{LP} = \text{median}(p_i)$. If there are no national level ports privately administrated, we consider $p_{LP} = 0$.

2.1.2 For a given network configuration $X$ we can now compute an efficiency index for the private port administration as:

$$p_P(X) = p_{NP}(X)^{k(N^P)}p_{RP}(X)^{k(R^P)}p_{LP}(X)^{k(L^P)}$$

where $k(N^P), k(R^P), k(L^P)$ represent the frequencies of private national, regional and local ports respectively.

2.1 For a given network configuration $X$ we can now compute an efficiency index for the private management as:

$$P(X) = E(X)p_P(X)$$

The highest such an index, the better the network configuration is.

2.2.1 For any network configuration there might exist specific lines that the public administration might subsidise (or administrate directly) in order to maintain a public service available although not profitable. For each such line $i \in S$ ($S$ being the set of subsidised lines) we consider the cost $c_i$ and the support $s_i$ provided by the public administration. For each such line we can compute an efficiency index

$$\forall i \in S, \ l_i = 1 - \frac{s_i}{c_i}$$
such that \( l_i = 0 \) corresponds to lines totally subsidised. For a given network configuration \( X \) we can compute an efficiency index of the public subsidising as

\[
l(X) = \text{median}(l_i(X))
\]

2.2.2.1 For each national level port administered by the public sector we can compute an efficiency index:

\[
\forall i \in N^B, \quad p_i = \max_i (0, 1 - \frac{c_i}{r_i})
\]

where:
- \( N^B \): is the set of national level ports administrated by the public sector;
- \( c_i \): is the administration cost of port \( i \);
- \( r_i \): is the income of port \( i \).

We can therefore compute the index \( p_{N^B} = \text{median}(p_i) \).

2.2.2.2 For each regional level port administrated by the public sector we can compute an efficiency index:

\[
\forall i \in R^B, \quad p_i = \max_i (0, 1 - \frac{c_i}{r_i})
\]

where:
- \( R^B \): is the set of regional level ports administrated by the public sector;
- \( c_i \): is the administration cost of port \( i \);
- \( r_i \): is the income of port \( i \).

We can therefore compute the index \( p_{R^B} = \text{median}(p_i) \).

2.2.2.3 For each local level port administrated by the public sector we can compute an efficiency index:

\[
\forall i \in L^B, \quad p_i = \max_i (0, 1 - \frac{c_i}{r_i})
\]

where:
- \( L^B \): is the set of local level ports administrated by the public sector;
- \( c_i \): is the administration cost of port \( i \);
- \( r_i \): is the income of port \( i \).

We can therefore compute the index \( p_{L^B} = \text{median}(p_i) \).
2.2.2 For a given network configuration $X$ we can now compute an efficiency index for the ports administrated by the public sector as:

$$p_B(X) = p_{NB}(X)^{k(NB)}p_{RB}(X)^{k(RB)}p_{LB}(X)^{k(LB)}$$

where $k(NB), k(RB), k(LB)$ represent the frequencies of public national, regional and local ports respectively.

2.2 For a given network configuration $X$ we can now compute an efficiency index for the public sector management as:

$$B(X) = l(X)p_B(X)$$

The highest such an index, the better the network configuration.

2 Given two network configurations $X$ and $Y$, we consider that $X$ is at least as good as $Y$ under the network efficiency criterion iff it is the case for both the private and the public sectors.

Denote by $S_2(X, Y)$ the binary relation “$X$ is at least as good as $Y$ on criterion 2”, we have:

$$S_2(X, Y) \text{ iff } P(X) \geq P(Y) \text{ and } B(X) \geq B(Y)$$

**NB.** Instead of the unanimity rule adopted here it is possible to privilege one of the two efficiency indices (the private or the public one) choosing one of the two as the criterion enabling the relation $S_2$ and endowing the other one with a veto power in the case the relevant efficiency index is below a given threshold.

The same ranking procedure used for criterion 1 is used also for criterion 2 in order to define a ranking on a given set ($\mathcal{F}$) of alternative network configurations.

3.1.1 Consider matrix $N_0$ (number of links with 0 connections for each couple of nodes of the network). We are able for each non zero entry of the matrix to associate a capacity $\pi_{ij}^{0R} = \sum_l \pi_{ijl}^{0R}$ where $\pi_{ijl}^{0R}$ stands for the capacity of vessel $l$ operating on the link $i - j$ (during the winter period, considered as the standard offer for the residents (R) of the nodes of the network).

Consider now matrix $N_{01}$ (number of links with at most one connections). Clearly to each non zero entry of $N_{01}$ we can associate a capacity $\pi_{ij}^{1R} = \min(\pi_{ix}^{0R}, \pi_{xj}^{0R})$ ($x$ being the intermediate node). By the same way, considering matrix $N_l$ (number of links with at most two connections), we
associate capacities \( \pi_{ij}^R = \min(\pi_{ix}^R, \pi_{xy}^R, \pi_{yj}^R) \) \((x, y\) being the intermediate nodes). Finally we can define a matrix \( C^R \) of capacities such that \( \pi_{ij}^R = \max(\pi_{ij}^0, \pi_{ij}^1, \pi_{ij}^t) \).

On the other hand we can (through the transportation model) make an estimation of the demand of transportation of the residents (we denote it as matrix \( D^R \) with entries \( d_{ij}^R \)). We are now able to build a matrix \( \Theta^R \) whose entries represent the saturation index of each link:

\[
\eta_{ij}^R = \max(0, 1 - \frac{d_{ij}^R}{\pi_{ij}^R})
\]

Clearly index \( \eta_{ij}^R \) value 0 occurs when the demand exceeds the capacity.

From matrix \( \Theta^R \) we are able to compute a diagram of frequencies as follows:

- \( \theta_{1}^R \): number of couples in \( \Theta^R \) such that \( \eta_{ij}^R \leq 0 \);
- \( \theta_{2}^R \): number of couples in \( \Theta^R \) such that \( 0.2 < \eta_{ij}^R \leq 0.4 \);
- \( \theta_{3}^R \): number of couples in \( \Theta^R \) such that \( 0.4 < \eta_{ij}^R \leq 0.6 \);
- \( \theta_{4}^R \): number of couples in \( \Theta^R \) such that \( 0.6 < \eta_{ij}^R \leq 0.8 \);
- \( \theta_{5}^R \): number of couples in \( \Theta^R \) such that \( 0.8 < \eta_{ij}^R \leq 1 \).

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) \((X \succ Y)\) iff:

\[
\frac{\theta_{1}^R(X)}{|\Theta^R|} < \frac{\theta_{1}^R(Y)}{|\Theta^R|} \text{ OR } \frac{\theta_{2}^R(X)}{|\Theta^R|} < \frac{\theta_{2}^R(Y)}{|\Theta^R|} \text{ OR } \frac{\theta_{3}^R(X)}{|\Theta^R|} < \frac{\theta_{3}^R(Y)}{|\Theta^R|} \text{ OR } \frac{\theta_{4}^R(X)}{|\Theta^R|} < \frac{\theta_{4}^R(Y)}{|\Theta^R|} \text{ OR } \frac{\theta_{5}^R(X)}{|\Theta^R|} < \frac{\theta_{5}^R(Y)}{|\Theta^R|} \text{ OR } \ldots
\]

\( \text{NB.} \) The same reasoning concerning the properties of the lexicographic comparison applies here also.

3.1.2 Consider again matrix \( D^R \) (the demand matrix) and specifically its reduction \( \Delta^R \) such that, \( \forall i, j \ d_{ij}^R > \delta \) \((\delta \) being a threshold to be defined).

Then for a given network configuration we can compute an index

\[
\rho^R(X) = \frac{|\{ij : d_{ij}^R > \delta \text{ and } \pi_{ij}^R = 0\}|}{|\Delta(X)|}
\]

that represents the ratio of “important links” \((\text{the ones where } d_{ij}^R > \delta) \) that are not satisfied \((\pi_{ij}^R = 0)\). The lowest the index, the better the network configuration.
3.1 Given any two network configurations \( X \) and \( Y \) we consider that \( X \) is at least as good as \( Y \) as far as the residents demand satisfaction is concerned (\( S_{3.1}(X, Y) \)) iff it is the case for criterion 3.1.1 and the index of criterion 3.1.2 is not superior to 0.6. More formally:

\[
S_{3.1}(X, Y) \text{ iff } S_{3.1.1}(X, Y) \text{ and } \rho^R(X) < 0.6
\]

3.2.1 Consider matrix \( N_0 \) (number of links with 0 connections for each couple of nodes of the network). We are able for each non zero entry of the matrix to associate a capacity \( \pi_{ij}^{0T} = \sum_l \pi_{ijl}^{0T} \) where \( \pi_{ijl}^{0T} \) stands for the capacity of vessel \( l \) operating on the link \( i - j \) (during the summer period, considered as the standard offer for the tourists \( T \) of the nodes of the network).

Consider now matrix \( N_{01} \) (number of links with at most one connections). Clearly to each non zero entry of \( N_{01} \) we can associate a capacity

\[
\pi_{ij}^{1T} = \min(\pi_{ix}^{0T}, \pi_{xj}^{0T}) \quad (x \text{ being the intermediate node}).
\]

By the same way, considering matrix \( N_t \) (number of links with at most two connections), we associate capacities

\[
\pi_{ij}^{tT} = \min(\pi_{ix}^{0T}, \pi_{xj}^{0T}, \pi_{xy}^{0T}) \quad (x, y \text{ being the intermediate nodes}).
\]

Finally we can define a matrix \( C_T \) of capacities such that

\[
\pi_{ij}^{T} = \max(\pi_{ij}^{0T}, \pi_{ij}^{1T}, \pi_{ij}^{tT}).
\]

On the other hand we can (through the transportation model) make an estimation of the demand of transportation of the tourists (we denote it as matrix \( D_T \) with entries \( d_{ij}^{T} \)). We are now able to build a matrix \( \Theta^T \) whose entries represent the saturation index of each link:

\[
\eta_{ij}^{T} = \max(0, 1 - \frac{d_{ij}^{T}}{\pi_{ij}^{T}})
\]

Clearly index \( \eta_{ij}^{T} \) value 0 occurs when the demand exceeds the capacity.

From matrix \( \Theta^T \) we are able to compute a diagram of frequencies as follows:

- \( \theta_1^T \): number of couples in \( \Theta^T \) such that \( \eta_{ij}^{T} \leq 0.2 \);
- \( \theta_2^T \): number of couples in \( \Theta^T \) such that \( 0.2 < \eta_{ij}^{T} \leq 0.4 \);
- \( \theta_3^T \): number of couples in \( \Theta^T \) such that \( 0.4 < \eta_{ij}^{T} \leq 0.6 \);
- \( \theta_4^T \): number of couples in \( \Theta^T \) such that \( 0.6 < \eta_{ij}^{T} \leq 0.8 \);
- \( \theta_5^T \): number of couples in \( \Theta^T \) such that \( 0.8 < \eta_{ij}^{T} \leq 1 \).

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) (\( X \succ Y \)) iff:

\[
\frac{\theta_1^T(X)}{|\Theta^T|} < \frac{\theta_1^T(Y)}{|\Theta^T|} \quad \text{OR} \quad \frac{\theta_1^T(X)}{|\Theta^T|} = \frac{\theta_1^T(Y)}{|\Theta^T|} \quad \text{and} \quad \frac{\theta_2^T(X)}{|\Theta^T|} < \frac{\theta_2^T(Y)}{|\Theta^T|} \quad \text{OR}
\]
\[
\frac{\theta_1^T(X)}{|\Theta^T|} = \frac{\theta_1^T(Y)}{|\Theta^T|} \quad \text{and} \quad \frac{\theta_2^T(X)}{|\Theta^T|} = \frac{\theta_2^T(Y)}{|\Theta^T|} \quad \text{and} \quad \frac{\theta_3^T(X)}{|\Theta^T|} < \frac{\theta_3^T(Y)}{|\Theta^T|} \quad \text{OR}
\]

...etc...

**NB.** The same reasoning concerning the properties of the lexicographic comparison applies here also.

### 3.2.2
Consider again matrix \(D^T\) (the demand matrix) and specifically its reduction \(\Delta^T\) such that, \(\forall i, j \; d_{ij}^T > \delta\) (\(\delta\) being a threshold to be defined).

Then for a given network configuration we can compute an index

\[
\rho^T(X) = \frac{|\{ij : d_{ij}^T > \delta \; \text{and} \; \pi_{ij}^T = 0\}|}{|\Delta(X)|}
\]

that represents the ratio of “important links” (the ones where \(d_{ij}^T > \delta\)) that are not satisfied (\(\pi_{ij}^T = 0\)). The lowest the index, the better the network configuration.

### 3.2
Given any two network configurations \(X\) and \(Y\) we consider that \(X\) is at least as good as \(Y\) as far as the tourists demand satisfaction is concerned \((S_{3.2}(X, Y))\) iff it is the case for criterion 3.2.1 and the index of criterion 3.2.2 is not superior to 0.7. More formally:

\[
S_{3.2}(X, Y) \quad \text{iff} \quad S_{3.2.1}(X, Y) \quad \text{and} \quad \rho^T(X) < 0.7
\]

### 3.3.1
Consider matrix \(N_0\) (number of links with 0 connections for each couple of nodes of the network). We are able for each non zero entry of the matrix to associate a capacity \(\pi_{ij}^{0CW} = \sum_l \pi_{ijl}^{0CW}\) where \(\pi_{ijl}^{0CW}\) stands for the trucks capacity of vessel \(l\) operating on the link \(i - j\) (during the winter period).

Consider now matrix \(N_{01}\) (number of links with at most one connections). Clearly to each non zero entry of \(N_{01}\) we can associate a capacity \(\pi_{ij}^{1CW} = \min(\pi_{ix}^{0CW}, \pi_{xj}^{0CW})\) (\(x\) being the intermediate node). By the same way, considering matrix \(N_{ij}\) (number of links with at most two connections), we associate capacities \(\pi_{ij}^{2CW} = \min(\pi_{ix}^{0CW}, \pi_{xj}^{0CW}, \pi_{yj}^{0CW})\) (\(x, y\) being the intermediate nodes). Finally we can define a matrix \(C^{CW}\) of capacities such that \(\pi_{ij}^{CW} = \max(\pi_{ij}^{0CW}, \pi_{ij}^{1CW}, \pi_{ij}^{2CW})\).

On the other hand we can (through the transportation model) make an estimation of the demand of transportation of the carriers (we denote it as matrix \(D^{CW}\) with entries \(d_{ij}^{CW}\)). We are now able to build a matrix \(\Theta^{CW}\) whose entries represent the saturation index of each link:
\[ \eta_{ij}^{CW} = \max(0, 1 - \frac{d_{ij}^{CW}}{\pi_{ij}^{CW}}) \]

Clearly index \( \eta_{ij}^{CW} \) value 0 occurs when the demand exceeds the capacity. In the same way we can compute an index for the summer period as far as the carriers demand is concerned

\[ \eta_{ij}^{CS} = \max(0, 1 - \frac{d_{ij}^{CS}}{\pi_{ij}^{CS}}) \]

and compute an overall index \( \eta_{ij}^{C} = \eta_{ij}^{CS} \eta_{ij}^{CW} \) thus defining a new matrix \( \Theta^C \)

From matrix \( \Theta^C \) we are able to compute a diagram of frequencies as follows:
- \( \theta_1^C \): number of couples in \( \Theta^C \) such that \( \eta_{ij}^{C} \leq 0.2 \);
- \( \theta_2^C \): number of couples in \( \Theta^C \) such that \( 0.2 < \eta_{ij}^{C} \leq 0.4 \);
- \( \theta_3^C \): number of couples in \( \Theta^C \) such that \( 0.4 < \eta_{ij}^{C} \leq 0.6 \);
- \( \theta_4^C \): number of couples in \( \Theta^C \) such that \( 0.6 < \eta_{ij}^{C} \leq 0.8 \);
- \( \theta_5^C \): number of couples in \( \Theta^C \) such that \( 0.8 < \eta_{ij}^{C} \leq 1 \).

Consider two alternatives \( X \) and \( Y \). Then \( X \) is better than \( Y \) (\( X \succ Y \)) iff:

\[ \frac{\theta_1^C(X)}{|\Theta^C|} < \frac{\theta_1^C(Y)}{|\Theta^C|} \quad \text{OR} \]

\[ \frac{\theta_2^C(X)}{|\Theta^C|} = \frac{\theta_2^C(Y)}{|\Theta^C|} \quad \text{and} \quad \frac{\theta_3^C(X)}{|\Theta^C|} < \frac{\theta_3^C(Y)}{|\Theta^C|} \quad \text{OR} \]

\[ \frac{\theta_3^C(X)}{|\Theta^C|} = \frac{\theta_3^C(Y)}{|\Theta^C|} \quad \text{and} \quad \frac{\theta_4^C(X)}{|\Theta^C|} < \frac{\theta_4^C(Y)}{|\Theta^C|} \quad \text{OR} \]

\[ \text{etc...} \]

**NB.** The same reasoning concerning the properties of the lexicographic comparison applies here also.

3.2.2 Consider again matrix \( D^{CW} \) (the demand matrix) and specifically its reduction \( \Delta^{CW} \) such that, \( \forall i, j \ d_{ij}^{CW} > \delta \) (\( \delta \) being a threshold to be defined).

Then for a given network configuration we can compute an index

\[ \rho^{CW}(X) = \frac{|\{ij : d_{ij}^{CW} > \delta \text{ and } \pi_{ij}^{0CW} = 0\}|}{|\Delta(X)|} \]
that represents the ratio of “important links” (the ones where $d_{ij}^{CW} > \delta$) that are not satisfied ($\pi_{ij}^{0CW} = 0$). The lowest the index, the better the network configuration.

In the same way we can compute an index for the summer period

$$\rho^{CS}(X) = \frac{|\{ij : d_{ij}^{CS} > \delta \text{ and } \pi_{ij}^{0CS} = 0\}|}{|\Delta(X)|}$$

enabling to define an overall index $\rho^{C}(X) = \rho^{CS}(X)\rho^{CW}(X)$

3.2 Given any two network configurations $X$ and $Y$ we consider that $X$ is at least as good as $Y$ as far as the carriers demand satisfaction is concerned ($S_{3.3}(X, Y)$) iff it is the case for criterion 3.3.1 and the index of criterion 3.3.2 is not superior to 0.7. More formally:

$$S_{3.3}(X, Y) \iff S_{3.3.1}(X, Y) \text{ and } \rho^{C}(X) < 0.7$$

3 Given any two network configurations $X$ and $Y$ we consider that $X$ is at least as good as $Y$ as far as the demand satisfaction is concerned ($S_{3}(X, Y)$) iff it is the case for criterion 3.3 and criterion 3.2 and there is no strong opposition from criterion 3.1. More formally

$$S_{3}(X, Y) \iff S_{3.3}(X, Y) \text{ and } S_{3.2}(X, Y) \text{ and } \neg V_{3.1}(X, Y)$$

where the situation of veto on criterion 3.1 may occur either because the index $\rho^{R}(X)$ is very bad, or because the ratio $\frac{\theta_{R}^{1}(X)}{|\Theta_{R}|}$ is very bad.

The same ranking procedure used for criterion 1 is used also in criterion 3 in order to define a ranking on a given set ($\mathcal{F}$) of alternative network configurations.

5 Conclusion

In this paper we present a detailed description of an evaluation model aimed to compare different scenarios of the maritime transportation network in Greece (mainly in the Aegean sea). The model is part of a larger decision support system to be used in the context of transportation policy establishment.

The key characteristics of the model can be summarised to the following two points.
1. An explicit reference to the group of actors, the behaviour of which is expected to be considered by the model. From this point of view the model could help to justify and explain priorities that one or more actors could establish or consider.

2. A flexible use of different aggregation procedures along the nodes of the hierarchy of evaluation criteria. It should be noted that in this version there have been established arbitrary “winning coalitions” in order to aggregate criteria to a higher level. However, such a choice has been done in order to facilitate the presentation of the model and the implementation of the prototype. For every day use of the model a procedure aiding the establishment of the “winning coalitions” has to be implemented.

The model has been conceptually and logically validated. The client considered that the model faithfully represents the way by which the scenarios should be evaluated. Further on the coherence for each family of criteria has been tested. The model is now undertaking an extensive experimental validation in order to check its different parameters and to verify its consistency.

Moreover, a number of theoretical problems are under investigation:
- general models for frequency distributions comparison when a preference ordering applies on the related histogram;
- comparison patterns of qualitative distributions.
